DATA DISCREPANCIES IN AND NEW EXCITMENTS FOR D+D, D+T, AND T+T FUSION REACTIONS

Kelson Jarvie, R. A. Hardekopf, Ronald E. Brown, F. D. Correll, and G. G. Olssen
Los Alamos Scientific Laboratory
Los Alamos, New Mexico 87545, USA

We investigate the accuracy of the basic fusion data for the reactions T(d,n)He, T(t,2n)He, D(d,n)He, and D(d,p)T in the 10-100 keV bombarding energy region of interest in the design of fusion reactors, magnetic or inertial. The history of the data base for these reactions, particularly the most critical one: T(d,n)He, is based on 25-year-old experiments whose accuracy (often assumed to be 5%) has rarely been questioned. In all except the d+d reactions significant discrepancies among data sets exist. The errors of the basic data sets may be considerably larger than previously expected and the effect on design calculations should be significant. Much of the trouble apparently lies in the accuracy of the energy measurements which are difficult at low energies. We feel that systematic errors of up to 50% are possible in the reactivity values of the present T(d,n)He data base. The errors in the reactivity would propagate proportionately into the errors in fusion probabilities in reactor calculations. The D(d,n)He and D(d,p)T cross sections appear to be well known and consistent. The T(t,2n)He cross section is poorly known and may be subject to large systematic errors. Improved absolute measurements in the 10-100 keV bombarding energy region for the above reactions are underway at Los Alamos. The experiment features a windowless cryogenic target, calibration of the target density with a high energy Van-de-Graaff beam, measurement of the beam intensity with a calorimeter, use of a negative ion source for the 10 to 100 keV measurements, and a time-of-flight laser spectrometer to determine the absolute energy. Both the source and target will be capable of handling tritium. Accuracies of better than 5% are anticipated.

Data survey

The T(d,n)He low energy data base rests on three main references. Arnold et al., at Los Alamos, measured $\sigma(90^0)$ down to about 10 keV (lab bombarding energy) claiming 2% accuracy. Since the reaction is isotropic in the c.m. system below several hundred keV, the $\sigma(90^0)$ is easily converted to an integrated cross section $\sigma_t$. Conner, Bonner, and Smith at Rice University measured $\sigma(90^0)$ down to 10 keV, with 3% accuracy, and Katsaurov at the Lebedev Institute measured $\sigma_t$ down to 45 keV claiming 2-3% accuracy. Earlier experiments like those of Jarvis, Groeneveld, and Roa in England (20-40 keV, about 10% accuracy) were adjudged to be in some disagreement with the later US. experiments and were not commonly used. Most data bases in fusion reactor calculations come eventually from the work of Arnold and Conner. The fractional error in the reaction rate in a burning plasma is expected to be equal to the fractional error in the cross section.

Figure 1 shows the T(d,n)He data. The line is an R-Matrix fit by Stewart and Hale which agrees with standard references 3 and 4, and excludes the Katsaurov data because of an apparent energy shift in the Russian data. Study of the details of Katsaurov's work indicate that it was a carefully done experiment with due regard to the difficult problem of measuring such a low energy. It is not clear in whose work the energy discrepancies lies. The circles, Katsaurov data, are seen to be shifted to lower energies by about 6 keV leading to a cross section discrepancy (standard values low) of 10-30% in the low energy region. Figure 2 shows the low energy detail. Included in this graph is a point by Jarvis and Roa which, if correct, would agree with the energy scale of Katsaurov. The Jarvis data were also not included in the Stewart and Hale report.
The accurate measurement of the bombarding energy is difficult at low energies and is suspected by us to be the main cause of the cross section discrepancies. Because the cross section is falling in a steep exponential, slight energy shifts can produce a large error in the cross section magnitude. One can calculate, for example, that at 20 keV, a shift of only 0.5 keV in the bombarding energy will produce a 10% change in the cross section. At the lower energies the fractional cross section error varies as $\Delta E/E^3/2$, so that the effect gets larger as the energy decreases.

The experimental equipment for the $T(d,n)^{4}\text{He}$ reaction was often used in the measurement of similar reactions which also show discrepancies. For example, the main U.S. groups: Bonner, Conner, and Lillie⁴, and Arnold³ et al., also measured the $3\text{He}(d,p)^{4}\text{He}$ reaction total cross section with essentially the same apparatus. Kunz¹⁰, in a subsequent experiment in the low-energy region, disagrees with the above data, having an apparent energy shift of from 5–15 keV higher so that his cross section values are 30–50% lower than the previous work.

It should be noted that Kunz normalizes his absolute scale by also measuring the $D(t,n)$ reaction with his equipment and normalizing to peak of the $T(d,n)$ measurement of Conner, Bonner, and Smith⁴. His agreement with Bonner, Conner, and Lillie at the peak of the resonance is then no surprise, but the disagreement at lower energies again indicates an energy measurement problem.

Detail of the low energy $3\text{He}(d,p)$ reaction is shown in Fig. 3. Again the work of Jarvis and Roed¹¹ disagree with the Rice and LASL experiments and agree with Kunz¹⁰. Note that the apparent energy shift of the "standard" work is in the direction opposite to the $T(d,n)$ case in Fig. 2.
An unpublished report of a measurement on the $^{3}$He($^{3}$He,$^{3}$He)$^{3}$He reaction was made in 1969 by Dwarakanath, in which he included a measurement of the $^{3}$He($^{3}$He,$^{3}$He)$^{3}$He total cross section. His data are not available in tabular form. Inspection of his unpublished results indicates, paradoxically, that his data agree with Arnold et al. and Bonner, Conner and Lillie at low energies.

The same accelerator and absolute energy measurement used in the Arnold et al. $^{3}$He($^{3}$He) measurement was used by Sawyer and Phillips in the $^{3}$Li($^{3}$He,$^{3}$He)$^{4}$He reaction. Figure 8 of Elwyn et al. shows the data of Sawyer and Phillips to be high by a factor of 2 or 3 in the 10 keV region compared to the data of Pfeiffer and Kunze and Suzanne and Ginow. It is not clear much of this discrepancy is due to a possible energy shift.

$^{3}$He($^{3}$He,$^{3}$He)$^{3}$He

Greene's compilation is again the source of data as used in the design codes. His work depends largely on Govorov et al. who measure $\sigma_T$ from 50 to 100 keV (5% accuracy). He omits the data of Agnew et al. (down to 40 keV) and the $\sigma(90\degree)$ 4% accuracy. Experiments done since Greene's publication are those of Strell'nikov et al. who measure $\sigma(90\degree)$ from 20 to 300 keV (5% uncertainty claimed) and Serov, Abramovich, and Morkin who measure $\sigma(10\degree)$ and $\sigma_2$ from 30 to 160 keV. Serov's numerical data are available. For completeness we should mention the work of Govorov et al. who measure $\sigma(90\degree)$ from 230 to 1000 keV; and the measurement of the neutron and alpha spectra by Bane and Leland, Wong, Anderson, and McClure, and Larose-Pouliassou, and Jarrel and Allen.

Low energy $^{3}$He($^{3}$He,$^{3}$He)$^{3}$He data are consistent and poorly understood. In some cases the total cross section is measured and sometimes the zero degree differential cross section. Comparison of the two kinds of data is not simple because the conversion between the two is not simple, even assuming isotropy in the o.m. system. The reason for this results from the 3-body breakup; and either an angular distribution must be measured or a model dependent calculation made. The conversion is also energy dependent.

In Fig. 4 the zero-degree differential cross section is presented to show the trend of the data. Shown is the prediction of the compilation of Duane which was derived from the Agnew data. The $\sigma_T$ data of Govorov, divided by 10 (which is thought to be a reasonable conversion, see the discussion in ref. 9) follows the Greene curve. The Serov, Abramovich, and Morkin data clusters around the Strelin'nikov curve. The prediction of Greene (divided by 10) is shown for comparison. It is seen that large differences occur between various data, leading to a considerable lack of reliability in the source of fusion-calculations data sets (Greene's compilation).

Stewart and Hale show that there are severe internal inconsistencies between the various sets of data concerning the conversion from $\sigma(90\degree)$ to $\sigma_T$. This may help explain that when the data are plotted as $\sigma_T$ vs energy they look somewhat less discrepant. An R-matrix solution by Hale, Young, and Jarrel to the total cross section data of ref's. 16, 20, and 25 up to 2 MeV leads to a prediction of the reactivity of the $^{3}$He($^{3}$He)$^{3}$He reaction about 50% smaller than that predicted by Greene, below 50 keV bombarding energy. The data in this low-energy region are dominated by the work of Serov et al. who made a concerted effort to measure the bombarding energy accurately. Even if they were successful at this difficult task, their energy error is still 2 to 3 keV, and the stated error in their cross sections are from 20 to 30%.

Considering the other inconsistencies mentioned, our knowledge of $^{3}$He($^{3}$He)$^{3}$He cross sections is not secure.

$^{3}$He($^{3}$He)$^{3}$He

Many experiments measuring absolute cross section have been done partially because of a report of a narrow resonance near $E_b = 100$ keV and the comparison of the two branches. Unlike the $^{3}$He($^{3}$He) and $^{3}$He($^{3}$He)$^{3}$He reactions the angular distribution is highly anisotropic at low energies. A good summary of the experiments is given by Theus.

McNeil has revised the total cross section data of Arnold et al. upwards by 3-12% to account for improved anisotropy measurements. When this done, the several absolute experiments agree within experimental errors which are generally 10-15% except for Arnold who quotes 2-5%. It seems then that the data for the $d + d$ reactions are in satisfactory agreement.

Fig. 4 The $^{3}$He($^{3}$He)$^{3}$He zero-degree differential cross section vs triton bombarding energy. Greene's (Ref. 7) total cross section prediction, based on Govorov (Ref. 16), is divided by 10 to give the curve shown. Duane's prediction (Ref. 26) is based on the Agnew data (Ref. 17). The Serov data (Ref. 20) closely follows the Strelin'nikov data (Ref. 18) represented by the solid line.
The d + d data of Arnold et al. were taken with the same apparatus as in their T(d,n) experiment. The apparent agreement of Arnold’s d + d data with the other experiments in that system adds another curious heuristic element in the question of the reliability of their T(d,n) data.

Cross Section Experiment

An experiment is now in progress at Los Alamos to measure the absolute cross sections of the reactions under discussion from 10-100 keV bombarding energy to an reliable accuracy of better than 5%. Since knowledge and control of the absolute energy is of some concern, great effort has been made in the design to achieve a good energy measurement.

The schematic of the experiment is shown in Fig. 5. There are several key elements in the experimntal design. 1. The target is a windowless, continuous flow, cryogenic device, with the outflowing gas trapped on 4% surfaces. The avoidance of windows is a critical factor in obtaining a reliable determination of the energy. The target will be capable of handling tritium. A typical target density is about 10^12/cm^3. Precise measurement of gas flow and target temperature is necessary. 2. Because of charge exchange in the target, the beam intensity will be measured by a precision resistor meter following a design by Thomas and Benn. 3. The 5-120 keV ion source will produce a negative beam to eliminate unwanted ion species and suppress effects of albedo scattering. It will be capable of accelerating tritons. Beam currents will be from 1-50 microamps. 4. Energy loss in the target will be explored with a laser spectrometer. This device uses a precise time-of-flight measurement of a beam pulse created by photodetachment of the beam negative ions with a pulsed Nd: YAG laser. Both the laser spectrometer and a precision resistor stack will be used to measure the absolute energy. An attempt will be made to keep all of the error in the beam energy less than 50 eV. Calibration of the target density will be made using a high energy Tandem Van-de-Graaff beam. A reaction with well known cross section, such as D(p,p)D or T(p,p)T, will be used. If necessary, the netting section of the experiment will be measured separately at Los Alamos to better than 1%.

At this writing, the cryogenic target is complete, the ion source installed and running, the calorimeter complete and tested and all of the beam optic elements installed. Both 100 keV and 10 MeV beams have successfully bombarded a deuterium target and reaction particles have been detected. The laser spectrometer and tritium handling equipment are under construction. A photograph of the system is shown in Fig. 6.

We plan to first measure the D + D system to work out problems in the system; then accelerate tritons to study D + T and finally flow tritium in the target to study the T + T reaction.

Acknowledgments

We would like to acknowledge helpful communications with A. M. Govorov, A. J. Elwyn, R. Santoro, G. M. Hale, L. Stewart, and O. A. Keyworth. The work of Rudy Martinez and Walt Sondheim has been essential in the construction of the apparatus.
